(Received 10 March 2003; published 16 June 2004)

We investigate various resummations of the chiral expansion and fit to the extremely accurate lattice QCD data for the mass of the nucleon recently obtained by the CP-PACS group. Using a variety of finite-range regulators, we demonstrate a remarkably robust chiral extrapolation of the nucleon mass. The systematic error associated with the chiral extrapolation alone is estimated to be less than 1%.

The application to baryons has developed to the point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical point where the chiral extrapolation to the physical

Hadronic physics presents fascinating theoretical challenges to the understanding of strongly interacting systems in terms of their fundamental degrees of freedom in QCD, quarks, and gluons. Lattice gauge theory [1] has so far provided the only rigorous method for solving nonperturbative QCD. We will show that recent progress within the field [2] together with advances in effective field theory (EFT) [3] now permit systematically accurate chiral extrapolations of observables, enabling the determination of the physical properties of hadrons from lattice QCD simulations, even though it is not yet feasible to make calculations at the physical quark mass.

It is now possible to make extremely accurate lattice QCD calculations of the masses of hadrons, such as the nucleon, with dynamical fermions. Indeed the CP-PACS group has just reported data with a precision of order 1% [2]. However, such precise evaluations are limited to quark masses an order of magnitude larger than those found in nature. In order to compare with experiment, which is after all one of the main aims in the field, it is therefore necessary to extrapolate in quark mass. Such an extrapolation is complicated by the unavoidable nonanalytic behavior in quark mass, which arises from Goldstone boson loops in QCD with dynamically broken chiral symmetry [4].

Early work motivated by the important role of Goldstone bosons led to the construction of chiral quark models [5], which incorporated this nonanalytic behavior. An alternative, systematic approach, designed to avoid reference to a model, involved the construction of an effective field theory to describe QCD at low energy [6]. The application to baryons has developed to the point where chiral perturbation theory (χPT) is now understood as a rigorous approach near the chiral limit [7,8].

Because it is defined as an expansion in momenta and masses about the chiral limit, χPT provides an attractive approach to the problem of quark mass extrapolation for lattice QCD. The advantages of formulating χPT with a finite-range regulator (FRR), as opposed to the commonly implemented dimensional regularization (DR), have been demonstrated by Donoghue et al. [9]. Early implementations of a FRR to evaluate chiral loop integrals in χPT suggested that, in the context of the extrapolation of lattice data from relatively large quark masses, FRR provides a more reliable procedure [10,11]. There has been considerable debate on whether current lattice data are within the scope of dimensionally regularized χPT or whether the form of the FRR chosen introduces significant model dependence [12]. However, this issue has now been addressed in a recent detailed study of numerous regularization schemes in χPT, both dimensional and FRR [3]. This study quantified the applicable range of the EFT and established that all of the FRR considered provided equivalent results over the range $m_q^2 \lesssim 0.8$ GeV$^2$.

Here we demonstrate that by adopting the FRR formulation of χPT one can improve its convergence properties to the point where the chiral extrapolation to the physical quark mass can be carried out with a systematic uncertainty of less than 1%. Given this remarkable result, the current errors on extrapolated quantities are dominated by the statistical errors arising from the large extrapolation distance—the lightest simulated pion mass being typically $m_\pi^2 \approx 0.27$ GeV$^2$, in comparison with the physical value, 0.02 GeV$^2$.

In the usual formulation of effective field theory, the nucleon mass as a function of the pion mass (given that $m_\pi^2 \propto m_q$ [13]) has the formal expansion

$$M_N = a_0 + a_2 m_\pi^2 + a_4 m_\pi^4 + a_6 m_\pi^6 + \cdots + \sigma_{NN}^\pi + \sigma_{N\Delta}^\pi + \sigma_{\text{tad}}^\pi. \quad (1)$$

In principle, the coefficients, $a_n$, can be expressed in terms of the parameters of the underlying effective Lagrangian to a given order of chiral perturbation theory. In practice, for current applications to lattice QCD, the parameters must be determined by fitting to the lattice results themselves. The additional terms, $\sigma_{NN}^\pi$, $\sigma_{N\Delta}^\pi$, and $\sigma_{\text{tad}}^\pi$, are loop corrections involving the (Goldstone) pion, which yield the leading (LNA) and next-to-leading nonanalytic (NLNA) behavior of $M_N$. As these terms involve the coupling constants in the chiral limit, which are essentially model independent [14], the only additional complication they add is that the ultraviolet behavior of the loop integrals must be regulated in some way.
Traditionally, one uses dimensional regularization, which (after infinite renormalization of $a_i$ and $a_2$) leaves only the nonanalytic terms, $c_{\text{LNA}} m^2_\pi$ and $c_{\text{NLNA}} m^4_\pi \times \ln(m_\pi/\mu)$, respectively. (Note that the coefficient $c_{\text{LNA}}$ is the sum of contributions from the $N \to \Delta \pi$ and tadpole diagrams.) Within dimensional regularization, one then arrives at a truncated power series for the chiral expansion,

$$M_N = c_0 + c_1 m^2_\pi + c_{\text{LNA}} m^4_\pi + c_4 m^4_\pi + \cdots,$$

(2)

where the bare parameters, $a_i$, have been replaced by the finite, renormalized coefficients, $c_i$. Through the chiral logarithm, one has an additional mass scale, $\mu$, but the dependence on this is eliminated by matching $c_4$ to "data" (in this case, lattice QCD). We work to fourth order in the chiral expansion and include the next analytic term to compensate short-distance physics contained in the NLNA loop integrals, as suggested in Ref. [9]. Provided the series expansion in Eq. (2) is convergent over the range of values of $m_\pi$ where the lattice data exist, one can then use Eq. (2) to evaluate $M_N$ at the physical pion mass. Unfortunately, there is considerable evidence that this series is not sufficiently convergent [3,12,15–17].

In line with the implicit $\mu$ dependence of the coefficients in the familiar dimensionally regulated $\chi$PT, the systematic FRR expansion of the nucleon mass is

$$M_N = a_0^\Lambda + a_2^\Lambda m^2_\pi + a_4^\Lambda m^4_\pi + a_5^\Lambda m^6_\pi + \sigma^\pi_{\text{NN}}(m_\pi, \Lambda) + \sigma^\pi_{\text{NN}}(m_\pi, \Lambda) + \sigma^\pi_{\text{NN}}(m_\pi, \Lambda),$$

(3)

where the dependence on the shape of the regulator is implicit. The dependence on the value of $\Lambda$ and the choice of regulator are eliminated, to the order of the series expansion, by fitting the coefficients, $a_i^\Lambda$, to lattice QCD data. The clear indication of success in eliminating model dependence, and hence having found a suitable regularization method, is that the higher order coefficients ($a_i^\Lambda$, $i \geq 4$) should be small and that the renormalized coefficients, $c_i$, and the result of the extrapolation should be insensitive to the choice of ultraviolet regulator.

The key feature of finite-range regularization is the presence of an additional adjustable regulator parameter which provides an opportunity to suppress short-distance physics from the loop integrals of effective field theory. This short-distance physics is otherwise treated incorrectly, as the effective fields are not realized in QCD at short distances. As emphasized in Eq. (3) by the superscripts $\Lambda$, the unrenormalized coefficients of the analytic terms of the FRR expansion are regulator-parameter dependent. The large $m_\pi$ behavior of the loop integrals and the residual expansion (the sum of the $a_i^\Lambda$ terms) are remarkably different. Whereas the residual expansion will encounter a power divergence, the FRR loop integrals will tend to zero as a power of $\Lambda/m_\pi$ as $m_\pi$ becomes large. Thus, $\Lambda$ provides an opportunity to govern the convergence properties of the residual expansion and thus the FRR chiral expansion. Since hadron masses are observed to be smooth, almost linear functions of $m_\pi^2$ for quark masses near and beyond the strange quark mass [18], it should be possible to find values for the regulator-range parameter, $\Lambda$, such that the coefficients $a_i^\Lambda$ and higher are truly small. In this case, the convergence properties of the residual expansion and the loop expansion are excellent and their truncation benign [19].

In order to investigate the model dependence associated with the truncations of the chiral expansions, several regulators are considered. We evaluate the loop integrals in the heavy baryon limit

$$\sigma_{\text{BB}} = -\frac{3}{16 \pi^2 f^2_\pi} G_{\text{BB}} \int_0^\infty \frac{dk}{k^2 u^2(k)}\frac{k^4 u^2(k)}{\omega(k)(\omega_{\text{BB}} + \omega(k))},$$

(4)

$$\sigma_{\text{BB}} = -\frac{3}{16 \pi^2 f^2_\pi} \left( \int_0^\infty \frac{dk}{k^2 u^2(k)} - t_0 \right),$$

(5)

taking $u(k)$ to be either a sharp cutoff, a dipole, a monopole, or finally a Gaussian. These regulators have very different shapes, with the only common feature being that they suppress the integrand for momenta greater than $\Lambda$. In Eq. (4) we have $G_{\text{NN}} = g_{\text{NN}}^2$ (with $g_{\text{NN}} = 1.26$) and $G_{\text{NL}} = 16 g_{\text{NL}}^2 / 9$ (to reproduce the empirical width of the $\Delta$ resonance). In addition, $\omega(k) = \sqrt{k^2 + m_\pi^2}$, $\omega_{\text{BB}} = 0$, and $\omega_{\text{NL}} = 292$ MeV, the physical $\Delta$-N mass splitting. In Eq. (5) $t_0$, defined such that the term in braces vanishes at $m_\pi = 0$, is a local counter term introduced in FRR to ensure a linear relation for the renormalization of $c_2$.

In addition, we also consider the case where Eq. (2) is modified to maintain the correct branch-point (BP) structure at $m_\pi = \omega_{\text{NN}}$ [20], in particular,

$$\sigma^\pi_{\text{NN}} = -\frac{3}{16 \pi^2 f^2_\pi} G_{\text{NN}} \left[ \frac{1}{4} \left( 2\Delta^3 - 3m^2\Delta \right) \log \left( \frac{m^2}{\mu^2} \right) \right]$$

$$- \frac{1}{2} \left( \Delta^2 - m^2 \right)^{3/2}$$

$$\times \log \left( \frac{\Delta - \sqrt{\Delta^2 - m^2}}{\Delta + \sqrt{\Delta^2 - m^2}} \right),$$

(6)

One can now compare the expansion about the chiral limit for these six different regularization schemes in order to assess their rate of convergence. It turns out that all the FRR expansions precisely describe the dimensional regularization expansion over the range $m_\pi^2 \in (0, 0.7) \text{ GeV}^2$. Furthermore, the smooth, FRR formulations are consistent with each other, for the renormalized chiral coefficients, $c_{0,2,4}$, to an extraordinarily precise level [3]. This ensures a systematically accurate extrapolation to the regime of physical quark masses.

For this study we use recent precision nucleon mass data obtained in lattice QCD by CP-PACS [2]. Simulations are performed using the mean-field improved clover fermion action with the Iwasaki gluon.
action, known to provide small scaling violations. We choose the largest volumes at the two smallest lattice spacings [21] such that the results are good approximations to the continuum theory. These data are used to determine the unknown parameters, \( a_0 \sim a_6 \), in Eq. (3) for each choice of regularization. Only in the naive, dimensionally regulated form, i.e., without the \( N \to \Delta \pi \) branch structure of Eq. (6), do the \( a_i \) coincide with the \( c_i \) of Eq. (2). It is only the extreme accuracy of the data which makes the determination of as many as four parameters possible.

Figure 1 shows the resulting fits to the lattice data over the range \( m_\pi^2 \in (0, 1.0) \text{ GeV}^2 \), with the corresponding parameters given in Table I. It is remarkable that all four curves based on FRR are indistinguishable on this plot. Furthermore, we see from Table I that the coefficient of \( m_\pi^4 \) in all of those cases is quite small—an order of magnitude smaller than the dimensionally regularized forms. Similarly, the FRR coefficients of \( m_\pi^6 \) are again much smaller than their DR counterparts. This indicates that the residual series, involving \( a_i \), is converging when the chiral loops are evaluated with a FRR.

**Table I.** Bare, unrenormalized, parameters extracted from the fits to lattice data displayed in Fig. 1. All quantities are in units of appropriate powers of GeV and \( \mu = 1 \text{ GeV} \) in Eq. (2). Dim. stands for dimensional and BP for the branch-point form defined in Eq. (6).

As explained by Donoghue et al. [9], one can combine the order \( m_\pi^{2,4...} \) terms from the self-energies with the “bare” expansion parameters, \( a_{0,2,4...} \), to obtain physically meaningful renormalized coefficients. These are shown in Table II, in comparison with the corresponding DR coefficients found using Eq. (2). Details of this renormalization procedure are given in Ref. [3]. The degree of consistency between the best-fit values found using all choices of FRR is remarkably good. On the other hand, DR significantly underestimates \( c_4 \). We can understand the problem very simply: it is not possible to accurately reproduce the necessary \( 1/m_\pi^2 \) behavior of the chiral loops (for \( m_\pi > \Lambda \)) with a third order polynomial in \( m_\pi^2 \).

It is clear that the use of an EFT with a FRR enables one to make an accurate extrapolation of the nucleon mass as a function of the quark mass. Although minimal deviation is seen between the best-fit curves, we need to determine how well these curves are in fact constrained by the statistical uncertainties of the lattice data. As all data points are statistically independent, the one-sigma deviation from the best-fit curve is defined by the region for \( (\chi^2 - \chi^2_{\text{min}})/\text{dof} < 1 \). We use a standard \( \chi^2 \) measure, weighted by the squared error of the simulated data point, and \( \chi^2_{\text{min}} \) corresponds to the optimum fit to the data.

[19] Note that $\Lambda$ is not selected to approximate the higher order terms of the chiral expansion. These terms simply sum to zero in the region of large quark mass, and the details of exactly how each of the terms enter the sum are largely irrelevant.
[21] We employ the UKQCD method [22] to set the physical scale, for each quark mass, via the Sommer scale $r_0 = 0.5$ fm [23,24].
[25] Our study has focused on the systematic errors associated with chiral extrapolation, while those arising from finite lattice spacing and volume remain to be quantified.
