Green OA applies to all our journal articles, but it is primarily designed to support OA for articles that are otherwise only available by subscription or other payment. For that reason, we are more restrictive in what we allow under Green OA in comparison with Gold OA:

- The final, published version of the article cannot be made Green OA (see below).
- The Green OA version of the article is made available to readers for private research and study only (see also Information for repositories, below). We do not allow Green OA articles to be made available under Creative Commons licences.

Funder policies vary in which version of an article can be made Green OA. We use the following definitions (adapted from the National Information Standards Organization – NISO):

Abstract

One of the major contributing factors to the continuous rise in obesity rates is the increase in caloric intake, which is driven to a large extent by the ease of access and availability of palatable high-fat, high-sugar ‘junk foods’. It is also clear that some individuals are more likely to overindulge in these foods than others; however, the factors which determine an individual’s susceptibility towards the overconsumption of palatable foods are not well understood. There is growing evidence that an increased preference for these foods may have its origins early in life. Recent work from our group and others has reported that \textit{in utero} and early life exposure to these palatable foods in rodents increased the offspring’s preference towards foods high in fat and sugar. One of the potential mechanisms underlying the programming of food preferences is the altered development of the mesolimbic reward system, a system which plays an important role in driving palatable food intake in adults. The aim of this review is to explore the current knowledge of the programming of food preferences, a relatively new and emerging area in the DOHAD field, with a particular focus on maternal overnutrition, the development of the mesolimbic reward system and the biological mechanisms which may account for the early origins of an increased preference for palatable foods.

\textbf{Key words:} reward, dopamine, opioid, programming
Introduction

According to the World Health Organisation (WHO), obesity rates have doubled since 1980, and obesity is now a major public health issue in both developed and developing nations.\textsuperscript{1} Whilst there are many factors contributing to this obesity epidemic, one of the major driving forces has been the increased availability and consumption of high-fat, high-sugar foods (‘palatable’ or ‘junk foods’) over this time.\textsuperscript{1-3} It is also clear, however, that some individuals are more likely to overindulge in these high-fat/high-sugar foods than others, and human studies have consistently reported that overweight and obese individuals exhibit a higher preference for these palatable foods compared to lean individuals.\textsuperscript{3-6} Given the importance of an increased preference for high-fat, high-sugar foods for an individual’s susceptibility to obesity in a society where these foods are readily available, understanding the biological mechanisms which underlie an increased preference for palatable foods has become an important area of research.

Whilst these mechanisms are still poorly understood, there is growing evidence to suggest that food preferences can have their origins early in life, and studies in both rodents and humans have reported associations between exposure to excess fat and/or sugar before birth or in early infancy and an increased preference for palatable foods in the offspring.\textsuperscript{7-8} One of the proposed mechanisms for the programming of food preferences involves the mesolimbic reward system in the brain which includes the nucleus accumbens (NAc) in the forebrain and ventral tegmental area (VTA) in the midbrain. These brain areas have been shown to be altered following acute and chronic high-fat, high-sugar intake in adult rodents, in a way analogous to drugs of abuse.\textsuperscript{9-11} This suggests that the propensity of an individual to overconsume palatable foods could be a result of altered function of these central reward systems following exposure to an inappropriate nutrient supply before birth and in early postnatal life.
This review will explore the programming of food choices in the offspring, with a particular focus on maternal overnutrition and recent studies which have attempted to determine the underlying mechanisms involved, and will present a summary of our current understanding of the critical periods in the development of the reward circuitry during which permanent alterations in the function of this pathway could be established.
Palatable food intake and the mesolimbic reward system

It is now well-recognised that the drive to consume energy dense, nutrient poor junk foods in excess of caloric requirements has a biological basis, and that these foods have the capacity to activate central reward pathways in the brain in a similar manner to alcohol and drugs of abuse. The key systems involved in mediating this effect are the dopaminergic and opioid signalling systems within the mesolimbic reward system.

The activation of dopamine and opioid signalling begins in the VTA, in which the cell bodies of dopaminergic neurons are located. Rewarding stimuli activate the reward system by binding to specific receptors located on dopamine neurons in the VTA. Activation of these systems by rewarding stimuli also promotes the release of endogenous opioids, which block the release of gamma-aminobutyric acid (GABA) from interneurons in the VTA that normally inhibit dopamine release. The inhibition of GABA release by opioids disinhibits dopaminergic neurons and leads to an increase in dopamine synthesis in the VTA. These dopaminergic neurons project to the NAc where dopamine is released. Termination of dopamine signalling occurs through active reuptake of dopamine by dopamine active transporters (DAT). Opioids also bind directly to their receptors located within the NAc to potentiate reward signalling in this region of the mesolimbic system. Both the direct and indirect actions of opioids, together with the activation of dopamine neurons, create the pleasurable feeling or ‘high’ associated with the consumption of palatable foods, which is considered to be responsible for driving the excess consumption of palatable, high-fat, high-sugar foods compared to non-palatable foods (Figure 1).

The apparent difficulty that some individuals experience in resisting junk foods has raised the question of what determines the susceptibility to overindulging in high-fat/high-sugar foods in
an individual, and whether differences within the mesolimbic reward system play a role. Whilst this is still not fully understood, there is now evidence that food preferences can be programmed very early in life and are determined, at least in part, by nutritional exposures which occur before birth and in early infancy.

Programming of food preferences

A world-wide series of epidemiological and experimental animal studies have demonstrated that exposure to either an inappropriately low or inappropriately high supply of nutrients in utero is associated with an increased risk of obesity later in life.\textsuperscript{16-19} Whilst early studies in the field of developmental programming focused primarily on the long term health impacts of exposure to a reduced nutrient supply before birth, the increase in the prevalence of overweight, obesity and diabetes during pregnancy has led to an increased focus on the effects of being exposed to an elevated supply of nutrients before birth on metabolic health of the offspring. In humans, clinical and epidemiological studies have consistently demonstrated that infants born to women who are overweight/obese and/or diabetic during pregnancy are heavier at birth and have an elevated risk of developing obesity and type 2 diabetes in both childhood and adult life.\textsuperscript{16, 20-21} The role of maternal overnutrition in the programming of obesity is supported by work in a number of animal models (see review\textsuperscript{22}) and these studies have begun to elucidate the mechanisms underlying this association.

These investigations have demonstrated that perinatal exposure to an increased nutrient supply is associated with altered food intake in the offspring. In rodents, feeding dams a high-fat, high-sugar diet during pregnancy and lactation results in altered development of the central neural network for appetite regulation in the offspring, and this is associated with persistent hyperphagia and increased body weight and fat mass throughout life.\textsuperscript{23-25} Importantly, the
hyperphagia in these programmed offspring is greatly exaggerated when the animals are exposed to a palatable diet after weaning.\textsuperscript{25-26} These observations suggested that prenatal exposure to highly palatable diets had the potential to shift not only the set point for appetite regulation, but also to increase the propensity of the offspring to overindulge in palatable foods in postnatal life.

A number of studies have set out to specifically test the impact of early life nutrition on food choices in the offspring and have provided direct evidence for the early programming of food preferences. Bayol and colleagues provided dams with a cafeteria diet consisting of a range of palatable foods during pregnancy and/or lactation, and demonstrated that offspring of ‘junk food’ fed dams consumed significantly more calories from junk food when given free access to a junk food diet after weaning when compared to offspring of dams fed a control diet.\textsuperscript{19} In our laboratory, we also found that offspring born to dams fed a cafeteria diet during pregnancy and lactation consumed more fat, but not more carbohydrate, compared to offspring from control dams when given free access to both a cafeteria diet and standard rat chow, and that this effect persisted from weaning until at least 3 months of age.\textsuperscript{27} Importantly, Vucetic and colleagues have reported an increased preference for fat and sugar in the offspring of high-fat fed dams even when they were weaned on a standard (low-fat) rat chow until adulthood.\textsuperscript{28} These results point to a persistent effect of early exposure to a palatable diet on the regulation of food preferences that is not easily reversed by nutritional interventions applied later in life.

To date, there have been limited attempts to investigate the relationship between perinatal nutritional exposures and patterns of dietary intake in later life in humans, largely because of the difficulty of obtaining reliable food intake data in human populations and of disentangling the biological influences of maternal diet during pregnancy with the maternal influence on
postnatal feeding behavior (social effects). Nevertheless, a study in the UK looking at 428 children of obese and lean parents have shown that offspring of obese parents have a higher preference for high-fat foods and less for vegetables at 4-5 years of age.\textsuperscript{29} Moreover, Brion and colleagues demonstrated that increased intake of fat, protein or carbohydrate during pregnancy was directly correlated with increased intake of the same macronutrient by the child at 10 years of age. This provided evidence to support the existence of a relationship between the macronutrient intake of women during pregnancy and the subsequent food preferences of their children. Importantly, paternal diet and maternal postnatal diet were only weakly correlated with offspring food intake,\textsuperscript{8} thus highlighting the importance of maternal diet during pregnancy in the programming of food preferences.

If we accept that food preferences can be programmed by the perinatal nutritional experience, it is then important to establish whether there are specific windows in development during which this programming is most likely to occur. To date, however, the critical windows for the programming of food preferences remain unclear, and determining this is complicated by the fact that our knowledge of the development of the central reward pathway remains incomplete. The results of studies by Teegarden and colleagues, however, demonstrated that mice exposed to a high-fat diet only during the first week after weaning exhibited a preference for high-fat foods in adult life. This suggests, therefore, that the critical window for the programming of food preferences may extend well after birth, at least in rodents.\textsuperscript{30} Whether it is possible to reverse the effects of perinatal exposure to a highly palatable diet on later food preferences by interventions applied after birth also remains an important question, and one which is of particular importance in designing potential strategies for reversing the long term effects of perinatal exposure to palatable foods in human infants.
Investigations into the mechanisms through which a maternal junk food diet leads to the preference for junk food in the offspring have focused on the effects on development of the mesolimbic reward system in rodent models. Even though brain development persists after birth in the rodent, which differs from human infants where brain development is largely complete at birth, these models have provided valuable information on the development of the various neuronal network/systems in the brain, including the mesolimbic reward system.

**The dopamine system**

**Rodent**

The development of the dopamine system in the rat begins during embryonic life but is not complete until approximately the third postnatal week and the system is thought to be highly plastic throughout this time. The first mesolimbic dopamine neurons can be identified in the rat brain as early as embryonic day 12, and by embryonic day 17 and 18, large dopamine axon bundles have begun to enter the striatum, which includes the NAc, to form a complex network of fibres. Whilst dopamine axons are established in fetal life, this innervation is not complete until after the third week of postnatal life. At birth, dopamine fibres in the NAc are present at a higher density than in adult rodents. During the first two weeks after birth, the main postsynaptic targets of dopamine neurons are dendrites. In the third week of postnatal life, the number of medium spiny neurons, which are the main neurons found in the NAc, rapidly increases and spine density peaks, allowing more synaptic connections to be made. By the end of the third week, dopamine neuron organisation is much like that observed in the adult rat (Figure 2).

Dopamine receptors are also present before birth in the rat, with the development of the dopamine receptor system in this model continuing into early neonatal life. Using *in situ*
hybridization, Schambra and colleagues showed that dopamine receptor D1 and, at a lower level, dopamine receptor D2 were both present in neural tissues of the fetal rat as early as gestational day 14. From day 7 to day 21 of postnatal life, D2 is expressed at significantly higher levels than the D1 in the NAc and the level of expression of the two receptors equalises during the fourth week after birth (Figure 2). The different ontogeny of development of the respective dopamine receptors is thought to be due to differences in the factors driving the expression of these two receptors during development, with expression of D1 being driven predominantly by dopamine levels, whilst dopamine seems to play only a limited role in the development of D2.

**Human**

There are few studies which have investigated the ontogeny of the dopamine system in humans, since these studies rely largely on tissues from medical terminations and are difficult to obtain. It has been established, however, that the development of the dopamine pathway in the fetus begins as early as 6-8 weeks gestation and the fetal striatum exhibits immunoreactivity for tyrosine hydroxylase (the rate limiting enzyme in dopamine synthesis) and mRNA expression of the D1 dopamine receptor by as early as 12 weeks gestation. By 21 weeks gestation, the D2 dopamine receptor can also be detected in the striatum, with peak expression being reached 1 month after birth and remaining higher than adult levels until 9-10 years of age. The dopamine active transporter (DAT) is present in the striatum by 32 weeks gestation, raising the possibility that dopamine signalling may already be functional at this stage of development.

**The opioid system**

**Rodent**
Similar to the dopamine system, components of the opioid system can be detected early in embryonic development in rodents, but opioid signalling is not fully mature until well after birth. The endogenous opioids, including proopiomelanocortin products, proenkephalin products and prodynorphin products are all present at low levels before birth in the rat brain and increase in concentration with age, generally reaching peak concentrations by the fourth postnatal week. In line with the increase in the abundance of opioid peptides, opioid receptor binding increases with age to peak at around the third to fourth postnatal week.

An elegant study by Spain and colleagues, using specific radiolabelled ligands for each opioid receptor subtype (µ, κ, δ), has demonstrated that the different receptor subtypes each have distinct profiles of expression in the brain during development. The µ-opioid receptor, which is the main receptor subtype involved in the activation of the reward system following the intake of palatable foods, shows an initial decrease in binding during the first four days after birth, followed by a steady increase and peaks at postnatal day 21 (Figure 2). Whilst the κ-opioid receptor is also present at birth, it exhibits a much slower increase in binding, with only a 2 fold increase by the fourth postnatal week. Unlike the other two opioid receptors, the δ-opioid receptor was not detected at birth and only appeared in the second week, followed by a rapid increase in expression until the fourth week after birth. This study is, however, limited by the fact that it did not look at specific brain regions. Interestingly, a related study looking at µ-opioid receptor ontogeny specifically in the NAc showed a peak in binding during the first four days after birth, followed by a steady decrease which, is in complete opposition to the forebrain findings presented by Spain and colleagues, suggesting that the development of the opioid system is region-specific. This binding pattern in the NAc is however, of particular interest given the importance of the NAc in reward behaviors.
Human

As is the case for the dopamine system, studies on the development of the opioid system in the human are limited. Opioid system development appears to begin slightly after that of the dopamine system, however much like dopamine, the endogenous opioid, β-endorphin, has been detected early in gestation and is thought to play a role in regulating fetal growth. By 12 weeks gestation, expression of another endogenous opioid, enkephalin, has been detected in the fetal striatum. The development of opioid receptors appears to occur well after the detection of endogenous opioids, with specific binding to the µ- and κ-opioid receptors occurring at 20 weeks gestation, followed by the appearance of the δ-opioid receptor.

The influence of maternal diet on reward circuitry development

The link between perinatal exposure to highly palatable diets and the increased preference for fat and/or sugar in the offspring has opened the question of the biological mechanism which underlies this association. The central pathways which control motivation and reward are an obvious target for the programming of food preference, and indeed several recent studies have provided evidence that a number of key components of this system are altered in juvenile and adult offspring exposed to a high-fat/high-sugar diet before birth. Naef and colleagues reported that the offspring of mothers fed a high-fat diet during the last week of gestation and during lactation had reduced dopamine release in the NAc in response to a drug stimulus and decreased expression of the D2 receptor in the VTA in adulthood, implicating altered dopamine signalling in the offspring. On the other hand, Vucetic and colleagues reported that a maternal high-fat diet during pregnancy and lactation was associated with an increased expression of the µ-opioid receptor and dopamine active transporter (DAT), decreased expression of D1, D2 and dopamine- and cAMP-regulated neuronal phosphoprotein (DARPP-32) in the NAc, suggesting
that both the opioid and dopamine systems are affected by exposure to a highly palatable diet during fetal and early postnatal development.\(^{28}\)

We have also recently carried out studies in our own laboratory in order to determine the effect of maternal junk food feeding on the expression of key components of the reward circuitry in the offspring after exposure to a junk food diet at weaning. Gene expression of the key components of the dopamine and opioid signalling systems was determined at 6 weeks (juvenile) and 3 months (adult) of age.\(^{27}\) An increase in \(\mu\)-opioid receptor expression and a reduction in DAT expression were observed in the NAc of 6 week old offspring of junk food fed dams. Furthermore, we recently found that the expression of the \(\mu\)-opioid receptor was already elevated at weaning in male offspring of junk food dams (Ong and Muhlhauser, unpublished observations, 2011). These results have led us to speculate that the increase in the expression of opioid receptors in the NAc of the offspring is the primary event through which maternal high-fat/high-sugar feeding drives the increased preference for fat in these offspring after birth. Interestingly, although not surprisingly, the changes in mRNA expression of \(\mu\)-opioid receptor and DAT observed at 6 weeks of age were completely reversed at 3 months of age, suggesting that there was a premature desensitisation of the reward system compared to the control offspring which were also weaned on junk food, an effect which would be expected to be associated with further increases in fat intake during adulthood.\(^{27}\)

In addition to the underlying molecular pathway, there are also conflicting opinions as to whether it is maternal overnutrition during pregnancy or the lactation/neonatal period that is the critical window for neuronal development. Bayol and colleagues found that offspring exposed to a junk food diet during suckling period consumed significantly more junk foods when they were weaned onto a junk food diet, compared to offspring exposed to a control diet
This highlights the sensitivity of the lactation period to nutritional excess and its contribution to the programming of increased energy intake and adult obesity. This is in contrast to a study conducted in Leibowitz’s laboratory, in which offspring of rat dams exposed to a high-fat diet during pregnancy, but not lactation, exhibited an increased expression of the endogenous opioid enkephalin in the hypothalamus at postnatal day 15, in conjunction with an increased preference for fat at postnatal day 50-60, whereas those exposed to a control diet in utero and a high-fat diet during lactation exhibited no such effects, suggesting that the prenatal period played the more important role in determining food preferences. These contrasting reports, together with the relatively small number of studies conducted in this field, create a need for further investigation into the mechanisms and critical windows for the programming of food preferences.

**Mechanisms for alterations of neonatal reward systems**

Emerging evidence has supported the hypothesis that being exposed to a high-fat, high-sugar environment before birth and/or during early in life can lead to alterations within the mesolimbic reward system, resulting in an increased preference towards these foods after birth. The exact mechanistic causes of these changes are, however, much less clear. One suggestion has been that tastes from the maternal diet are transmitted to the fetus/neonate via the amniotic fluid and breast milk and influence the development of taste receptors such that the offspring develop an increased preference for these flavours after weaning. The transmission of flavours, in particular strong flavours such as garlic, to the amniotic fluid and breast milk has been demonstrated in an elegant series of studies by Mennella and colleagues which have provided evidence that neonates exposed to these specific flavours before birth exhibited an increased preference for the same flavour after weaning. However, the programming of food preferences by exposure to specific tastes during the perinatal period is not supported by all
In work conducted by our laboratory, for example, we reported that the selection of junk foods favoured by the offspring of junk food fed dams was distinct from those favoured by the dam during pregnancy and lactation, suggesting that the programming of food preferences was macronutrient-specific and not related to taste. Therefore, further studies are required in order to clarify the role of taste in the programming of food preferences.

Another important, and as yet unanswered question, is whether there are distinct roles of specific macronutrients in the maternal diet, in particular fat and sugar, in the programming of food preferences in the offspring. Teegarden and colleagues previously demonstrated that weanlings given 10 days exposure to a high-fat diet had an increased preference for these foods as adults, but the same effect was not observed for those offspring provided with a high-carbohydrate diet during this same period. Given the contradicting and limited evidence available, it has been proposed that the effects of maternal palatable diets on the reward system are likely to be mediated indirectly through hormones such as leptin, insulin and ghrelin, as well as neuropeptides including orexins, GABA, serotonin and endogenous opioids which have all been shown to play a role in reward in adult rodents (see review). Since leptin, insulin and endogenous opioids have been implicated in the development of neural systems including the central appetite regulating network, they will be the focus of the remainder of the current review.

Leptin in the adult has a key role in energy homeostasis, acting in large part through the hypothalamic appetite regulating system, to inhibit appetite (For reviews see:). Importantly, leptin’s anorexigenic effects have been shown to be partially mediated by regulation of reward systems. Leptin receptors co-localise with dopaminergic neurons in the VTA and, in rodents, leptin infusion directly into the VTA suppresses food intake whilst peripheral leptin
administration completely inhibits high-fat food conditioned place preference. In the fetus and neonate, leptin is thought to play a greater role in the development of neural systems than in the regulation of appetite or reward, since leptin administration to rat pups during the first 9-10 days after birth has no effect on food intake. The timing of this apparent insensitivity to the actions of leptin coincides with a distinct surge in circulating leptin levels, which occurs between 7 and 10 days in rodents. Interestingly, the leptin surge has been shown to be exaggerated in both its magnitude and duration in offspring of obese dams fed a high-fat diet during pregnancy and lactation, and this is thought to contribute to the hyperphagia observed in these offspring later in life.

The role of leptin as a neurotropic signal in the central neural network for appetite regulation has been elegantly demonstrated by the work of Bouret and colleagues, in which leptin deficient mice (Lepob/Lepob) were shown to have a reduced density of neural projections within the appetite regulating system, and that this deficit could be completely reversed by administration of leptin to these mice during the neonatal period (i.e. the principal period of neuronal development). Importantly, administering leptin in adult Lepob/Lepob mice (after neuronal development was completed) had no effect on neuronal density or appetite in these animals. The similar regulatory functions leptin plays in both the reward and appetite circuitries of adults has led to the suggestion that leptin may have a similar developmental role in reward pathways. This is supported by studies showing that Lepob/Lepob mice have reduced dopamine release upon electrical stimulation of dopaminergic cells, possibly due to a deficiency in somatodendritic dopamine stores in the VTA of these mice. Moreover, a study conducted by Sanchez and colleagues showed that rat offspring treated with leptin during the lactation period exhibited a lower preference for fat in adulthood. This provides support for
the suggestion that exposure to high or low leptin concentrations early in life can alter subsequent food preferences in the offspring.

In addition to acting directly on the mesolimbic reward system, leptin may also act through indirect mechanisms, including its regulation of lateral hypothalamic orexin neurons, to impact foods choices of offspring after birth. In adults, orexin neurons input directly into the VTA and the NAc shell and it has been shown that orexin activity in the VTA is needed to mediate the preference for high-fat food caused by opioid receptor activation. Consequently, Kelley and colleagues proposed an integrated hypothalamic-thalamic-striatal model for the regulation of food reward and it is possible that the development of these connections could be altered by exposure to an excess supply of palatable foods in early life. A study by Beck and colleagues demonstrated that the offspring of mothers who consumed a high-fat diet throughout pregnancy and lactation had an increased preference for fat and an increased expression of orexin mRNA in the lateral hypothalamus compared to control animals at weaning and that this expression was inversely proportional to circulating leptin concentrations in these animals. Therefore, the actions of leptin, both direct and indirect, appear to play an important role in the development of the reward circuitry to influence food choices in the offspring after birth.

Insulin plays an important role in the maturation of neurons within the central nervous system and insulin receptors are expressed on neurons and astrocytes during early neuronal development. Similar to leptin, perinatal hyperinsulinaemia is associated with impaired organisation of the hypothalamic appetite regulatory network, which can lead to hyperphagia and the development obesity later in life. The connection between insulin and the development of the mesolimbic reward system is however, less well-defined. Nevertheless, in adult rodents, insulin receptors are found to co-localise with dopaminergic neurons in the
indicating a potential role of insulin in modulating dopamine activity within the mesolimbic reward pathway. Indeed, insulin has been shown to increase the expression and activity of DAT\(^{68}\) and hypoinsulinaemia induced by drugs or fasting reduces dopamine clearance in the striatum,\(^{69-70}\) which is associated with impaired insulin signalling and decreased DAT function.\(^{69,71}\) The role of insulin in mediating dopamine function and reward is consistent with the observation that insulin administration decreases sucrose self-administration\(^{73}\) and conditioned place preference to high-fat foods in rats.\(^{52}\) Maternal obesity and overnutrition are associated with increased maternal and fetal glucose and insulin concentrations.\(^{74,75}\) Therefore, given the role of insulin in neuronal maturation and organisation of the hypothalamic pathways, as well as its influence role in the regulation of food reward, it is possible that perinatal hyperinsulinaemia could alter the development of the mesolimbic reward system in the offspring and therefore result in an increased preference for palatable foods later in life. However, the role of insulin in the programming of food preferences remains to be demonstrated experimentally.

It has been previously established that exposure to morphine in utero can alter the reward circuitry of fetus and offspring, raising the possibility that increases in endogenous opioids could have similar effects.\(^{76}\) Prenatal and early neonatal exposure to morphine have been demonstrated to result in decreases in \(\mu\)-opioid receptor expression in early life\(^{77-78}\) and increased \(\mu\)-opioid receptor expression in adult life.\(^{79-80}\) Previous studies have shown, however, that the effects of endogenous and exogenous opioids may not always be the same\(^{81-82}\) and therefore whether these effects can be replicated through increased exposure to endogenous opioids remains to be determined. Increases in endogenous opioids, particularly met-enkephalin have been observed in the NAc of rats consuming a high-fat diet\(^{83}\) and, since opioids readily cross the placenta,\(^{84}\) increases in maternal met-enkephalin would be expected to result
in increased concentrations of met-enkephalin in the fetal circulation. Indeed, the offspring of mothers fed on a high-fat diet have been shown to have an increased abundance of met-enkephalin 15 days after birth.\textsuperscript{23} The idea that increases in neonatal enkephalin may program changes in reward circuitry development are supported by studies looking at the reward associated behaviors of adults administered met-enkephalin in early life. Kastin and colleagues demonstrated that adult rats administered met-enkephalin in the first week of life had improved maze performance for a food reward when compared to control animals.\textsuperscript{85} Similarly, administration of met-enkephalin together with exposure to an odor stimulus \textit{in utero} led to increased preference for the same odour at 16 days of age.\textsuperscript{86} These studies suggest a possible role for met-enkephalin in programming the developing reward circuitries of the offspring of mothers fed a palatable diet during pregnancy and lactation.

Summary and Perspectives

The concept that appetite can be permanently altered by exposure to an inappropriate supply of nutrients before birth has been established across a number of species. More recently, a number of studies have shown that not only overall food intake, but also an individual’s preference for specific foods/macronutrients, can be influenced by the nutritional environment experienced before birth and early in life. A summary of the current hypothesis for the programming of food preferences is shown in Figure 3. The ability of perinatal exposure to an increased supply of fat and/or sugar to program an increased preference for palatable foods in the offspring is of particular relevance given the ready availability of these foods in modern society, and the fact that excess consumption of these foods is a major contributor to weight gain, obesity and its associated metabolic disorders. At present, our understanding of the biological/molecular mechanisms which underlie the programming of food preferences is
limited, and further studies are required. Whilst this review has highlighted several possible mechanisms for the programming of food preferences, this list is not exhaustive and further research is expected to provide insights into alternate biological pathways. By way of example, a recent study has indicated a role for epigenetics in the maternal high-fat diet programming of food preferences. Given that consumption of high-fat diet is associated with epigenetic modification of the dopamine and opioid signalling systems within the mesolimbic reward pathway in adults, it is possible that this may also be one of the mechanisms through which food preferences are programmed before birth and in early life.

Whilst rodents provide a convenient model for delineating these mechanisms, the extent to which these will reflect the situation in humans is still unclear, and further studies mapping the development of the reward pathways in rodents and humans (and potentially other species) are required in order to be able to extrapolate the results of small animal studies into the clinical setting. Furthermore, virtually all studies to date which have focused on the reward pathway, be it in relation to its function in adults, development or response to prenatal nutritional alterations, have been carried out in males, and preliminary data from our own laboratory has shown that there are clear differences between males and females in their response to a junk food diet in adulthood and to exposure to a high-fat diet in utero.

There is still a great opportunity for studies in this field, and identifying strategies for intervention to block or inhibit the early programming of an increased preference for fat/sugar has the potential to offer a novel and effective means of curtailing the obesity epidemic.

Figure 1: Simplified version of the activation of the mesolimbic reward system. 1) A rewarding stimulus such as drugs and palatable foods can stimulate the dopamine neurons at the VTA, resulting in the release of dopamine at the NAc. 2) The rewarding stimulus can activate the release of endogenous opioids at the VTA, which inhibits GABA-ergic interneurons. GABA normally inhibits dopamine release. Therefore, this inhibition of GABA release disinhibits dopamine neurons resulting in increased dopamine release at the NAc. 3) Opioids can also bind to their receptors located at the NAc. The activation of efferent target neurons at the NAc through 1), 2) and 3) creates the pleasurable feeling associated with the rewarding stimuli. Black and grey arrows indicate neuronal activation and inhibition respectively. Neurons are represented in the circles.

Figure 2: Ontogeny of dopamine and opioid systems. Timeline depicting the development of the dopamine (top) and opioid (bottom) systems within the mesolimbic reward system throughout prenatal and the first 3 weeks of postnatal life in the rodent. By postnatal week 3, dopamine and opioid systems are similar to that of an adult. Abbreviations: DA, dopamine; E, embryonic day; NAc, nucleus accumbens; MSN, medium spiny neuron; PNW, postnatal week; VTA, ventral tegmental area. See text for references.

Figure 3: Current hypothesis for the early origins of a taste for fat. A maternal high-fat, high-sugar diet during pregnancy and lactation can lead to the increase in levels of leptin, insulin and endogenous opioids which can pass through the placenta (during pregnancy) and milk (during lactation) to the offspring. The elevated leptin, insulin and opioid levels in the offspring is postulated to alter the development of the mesolimbic reward system, during its critical windows of development, when the neuronal connections are actively developing. This can
result in permanent alterations in opioid and dopamine signalling which is associated with the increased preference for fat throughout life. This continuous consumption of high-fat foods can eventually lead to the onset of later obesity.
