Using hinged ligands to target structurally flexible copper(II) MOFs

Witold M. Bloch,*Christian J. Doonan* and Christopher J. Sumby*

Here we report two new flexible MOFs based on a bis-pyrazolylmethane 'hinged' link design that favours the formation of two distinct structural nodes within the resulting 2-D and 3-D structures. The less sterically demanding ligand H₂bcppm affords a 2-D layered MOF, 

{Cu₂[NO₃]₂(bcppm)]·2(DFM)}·2DMF (1), constructed from copper(II) paddlewheel and mononuclear octahedral copper(II) nodes. The use of a more sterically encumbered tetramethyl analogue

H₂bcpdmpm induces a dramatic twisting of the ligand backbone that yields a 3-D MOF[Cu₄(bcppm)]·2(DMF)·12H₂O (2) formed from a very similar mix of nodes, specifically copper(II) paddlewheel clusters and mononuclear tetrahedrally coordinated copper(I) centres. Herein we describe the crystal structures, solid-state flexibility, and gas adsorption properties of both materials.

Introduction

Flexible metal–organic frameworks (MOFs) have attracted significant attention as their dynamic structures give rise to properties that are not accessible for rigid architectures. Such materials, sometimes called third generation porous coordination polymers (PCPs), show 'gated’ adsorption behaviour that results in remarkable, pressure dependent, selective gas uptake. In addition, structural flexibility in MOFs, has facilitated the preparation of chemical sensors, and materials for controlled release of active pharmaceuticals. Structural flexibility can be introduced into MOF materials via judicious choice of metal nodes, non-rigid organic links, or by utilising weak non-covalent interactions between two or more interpenetrated frameworks. As part of our investigations into flexible solid-state materials, we reported the synthesis of a flexible material comprised of silver(I) and a di-2-pyrazinylmethane (dpzm, Figure 1) organic building block. This organic moiety possesses a methylene 'hinge' between two pyrazine donors where one nitrogen donor from each pyrazine ring can chelate a single metal while the other two donors can coordinate to two further metal centres. Significantly, the relative positions of the two bridging donor nitrogen atoms can be controlled through changes in the coordination geometry of the chelated metal. The reported 3-D CPB undergoes crystal-to-crystal breathing upon solvent exchange and, in the case of the particular example reported, a 3-D to 2-D structural change. Building on our earlier work, we have extended the hinged link approach to ligands capable of providing more chemically and thermally stable MOFs. Reaction of bcppm (Figure 1) with Cu(NO₃)₂ yielded the extended network [Cu(bcppm)]·2H₂O. Heating the as-synthesised material under vacuum generated a locked and pore constricted version of the framework that displayed exceptional CO₂/N₂ selectivity. We note that this is a rare example of utilising symmetrical bis-pyrazolylmethane building blocks in the synthesis of extended network materials.

In this manuscript we report two new flexible MOFs based on a bis-pyrazolylmethane 'hinged' link design that allows the incorporation of two distinct copper nodes within their 2-D and 3-D structures. The less sterically demanding ligand H₂bcppm affords a 2-D MOF with staggered layers, {Cu₂[NO₃]₂(bcppm)]·2(DFM)}·2DMF (1), while the more sterically encumbered tetramethyl analogue H₂bcpdmpm yields a self-penetrating 3-D MOF, 

{Cu₄[NO₃]₂(bcpdmpm)]·2(DFM)·12H₂O (2). The structures, solid-state flexibility, and gas adsorption properties of both materials are reported.
### Experimental

#### General Experimental

Elemental analyses were performed by the Campbell Microanalytical Laboratory at the University of Otago. Thermogravimetric analysis was performed on a Perkin−Elmer STA-6000 under a constant flow of N₂ at a temperature increase rate of 10°C/min. Infrared (IR) spectra were recorded on a Perkin−Elmer Fourier−Transform Infrared (FT−IR) spectrometer on a zinc−selenide crystal. NMR spectra were recorded on a Varian 600 MHz spectrometer at 23°C using a 5 mm probe. Unless otherwise stated, all chemicals were obtained from commercial sources and used as received. The compounds bis(4-(4-carboxyphenyl)-1H-pyrazolyl)methane (H₂bcppm)²² and bis(3,5-dimethyl-4-ido-1H-pyrazol-1-yl)methane (3)²⁵ were prepared by reported procedures.

#### Synthesis

The resulting mixture was heated at 85°C for 16 hours, giving teal rod-like crystals suitable for X-ray crystallography. The crystals were washed with methanol (× 8) followed by dichloromethane (× 8), after which they were dried under N₂ flow, and heated at 50°C under vacuum overnight (17.0 mg, 63% based on analysis for [Cu₂(C₅H₁₀N₂O₂)₂(H₂O)₂(NO₃)₂·2H₂O]. Found C 50.0, H 4.4, N 10.4. C₁₀H₁₀N₄O₆Cu₄ requires: C 50.3, H 4.4, N 10.6%.

#### X-ray Crystallography

Single crystals were mounted in paratone-N oil on a plastic loop. X-ray diffraction data were collected at 150(2) K on the MX1 beamline of the Australian Synchrotron (λ = 0.7107 Å). Data sets were corrected for absorption using a multi-scan method, and structures were solved by direct methods using SHELXS-97²⁶ and refined by full-matrix least squares on F² by SHELXL-97.²² Interfaced through the program X-Seed.²⁷ In general, all non-hydrogen atoms were refined anisotropically and hydrogen atoms were included as invariants at geometrically estimated positions, unless specified otherwise in additional details below. Figures were produced using the program CrystalMaker. CCDC 945926 and 945927 contain the supplementary crystallographic data for these structures. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

---

### Special Refinement Details for 1

Two of the nitrate anions (on special positions) were refined with isotropic displacement parameters and eight DFIX restraints were used to force chemically sensible bond lengths for these anions and a DMF molecule. The structure has large solvent accessible voids. These contained a number of diffuse electron density peaks that could not be adequately identified and refined as solvent. The SQUEEZE²⁹ routine of PLATON was applied to the collected data, which resulted in significant reductions in R₁ and wR₂ and an improvement in the GOF. The contents of the solvent region calculated from the result of SQUEEZE routine equates to two DMF per asymmetric unit. The ADDSYM routine detects pseudo-symmetry for the structure with a low fit (81% of atom positions fulfil this symmetry element). From the structure it is clear that the different positions of the DMF ligands on the copper(II) paddlewheel units, twisting of the ligand molecules, and dissimilar coordination environments about the tetrahedral copper(I) centres, which are all a consequence of layer-layer steric constraints, break this additional symmetry element.

### Special Refinement Details for 2

The carbon atoms of the two coordinated ethanol molecules were refined with isotropic displacement parameters and two DFIX restraints were used to achieve chemically sensible C=O bond lengths. The structure has very large solvent accessible voids. These contained a number of diffuse electron density peaks that could not be adequately identified and refined as solvent. The SQUEEZE²⁹ routine of PLATON was applied to the collected data, which resulted in significant reductions in R₁ and wR₂ and an improvement in the GOF. The contents of the solvent region calculated from the result of the SQUEEZE routine equates to two nitrate anions and 12 DMF molecules per asymmetric unit.
Powder X-ray diffraction data for 1 was collected on a Rigaku Hiflex Homelab system using Cu-Kα radiation with an R-Axis IV++ image plate detector. Samples were mounted on plastic loops using paratone-N and data collected by scanning 90° in phi for 120-300 second exposures. The data was converted into xye format using the program DataSqueeze. PXRD data for 2 was collected at the Australian Synchrotron on the Powder Diffraction (PD) beamline. The sample was prepared in a glass capillary (0.3 mm) and exposed to X-rays with a wavelength of 0.82544 Å. For further details on the instrument set-up see www.synchrotron.org.au. Simulated powder X-ray diffraction patterns were generated from the single crystal data using Mercury 2.4.

Gas adsorption measurements

Gas sorption isotherm measurements were performed on an ASAP 2020 Surface Area and Pore Size Analyzer. Activation of 1 was achieved by washing in DMF (x 3), methanol (x 8), and dichloromethane (x 8), drying under N$_2$ flow, and heated at 50°C under vacuum overnight. Similarly, a sample of 2 was activated by being washed with methanol (x 8) followed by dichloromethane (x 8), after which it was dried under N$_2$ flow, and heated at 50°C under vacuum overnight. UHP grade (99.999%) N$_2$ and CO$_2$ were used for all measurements. The temperatures were maintained at 77 K (liquid nitrogen bath), 195 K (acetone-dry ice bath), 273 K (ice-water bath), or 293 K (room temperature water), respectively. CO$_2$ enthalpy plots were obtained from isotherms collected at 273 and 293 K.

Results and Discussion

The previously reported MOF synthesised from the H$_2$bcppm ligand, [Cu(bcppm)H$_2$O]$_x$ $S$ (S = solvent),$^{22}$ required aqueous reaction conditions (25% H$_2$O$_2$). Excluding water from the solvent system led to the formation of a new MOF material [Cu$_2$(bcppm)$_2$][NO$_3$]$_2$:2DMF (1). Reacting H$_2$bcppm with Cu(NO$_3$)$_2$:2H$_2$O in a mixture of DMF, EtOH, and a few drops of 70% HNO$_3$ at 85°C gave a green micro-crystalline powder of 1 in 65% yield (Figure 2, top). The chemical composition of 1 was confirmed by elemental analysis of a dried sample (C$_{42}$H$_{38}$N$_{10}$O$_{10}$Cu$_2$S). Single crystals of 1 were obtained by reacting Cu(NO$_3$)$_2$:2H$_2$O and H$_2$bcppm in a mixture of DMF, EtOH, and a few drops of acetic acid at 65°C. These crystals were not suitable for in-house X-ray sources and thus structure elucidation was achieved using synchrotron radiation.

Figure 2. PXRD patterns for 1 (top): (a) simulated from the single crystal structure, (b) as synthesised, and (c) the activated material [Cu$_2$(bcppm)$_2$][NO$_3$]$_2$:2DMF (1'). PXRD patterns for 2 (bottom): (a) simulated from the single crystal structure, (b) as synthesised, and (c) the activated material [Cu$_2$(bcppdmpm)$_2$][NO$_3$]$_2$:2DMF (2').

The network topology of 1 is best described as a 2-D 4$^4$ net (Figure 3a) formed from bcppm and two distinct copper(II) nodes. Compound 1 crystallises in the orthorhombic space group Pnma with an asymmetric unit that contains two molecules of bcppm, four copper(II) centres (two on special positions), two coordinated DMF molecules and three nitrate anions (two on special positions). Two of the copper(II) centres form a dimetalllic

Figure 3. a) A view of the 2-D 4\(^4\) net in 1 along the c-axis. Views of the staggered 4\(^4\) nets of 1 along b) the c-axis and c) the b-axis. Hydrogen atoms removed for clarity.

paddlewheel cluster capped by DMF ligands, while the other two copper(II) centres are octahedral and coordinated by two chelating bis-pyrazolylmethane moieties and two monodentate nitrate anions. It is noteworthy that 1 is comprised of two distinct metal nodes yet is synthesised from one type of ligand, albeit one with distinct coordination sites, and a single metal salt. The 2-D layers of 1 span ca. 15.2 × 19.0 Å between octahedral copper(II) centres and Cu\(_2\) paddlewheel dimers respectively. Close inspection of the structure shows that the 2-D layers of 1 pack in a staggered formation that prevents open channels along the a, b, and c axis (Figures 3b and 3c). The 2-D layers of 1 are held in position by van der Waals interactions that occur between a coordinated DMF solvate molecule and a carbon (phenyl ring) of bcppm, with a distance of 2.871 Å.

Interestingly, co-planarity of pyrazole and phenyl rings for bcppm is observed in the 2-D structure of 1. In order to explore the topological transformation that would result from perturbing this structural feature, we synthesised the tetramethyl substituted ligand H\(_2\)bcpdmpm following our established conditions. We hypothesised that the additional steric bulk of the methyl groups would lead to a permanent twist in the backbone of the ligand, and thus promote a different geometrical arrangement. H\(_2\)bcpdmpm is substantially more soluble than H\(_2\)bcppm but nonetheless, by modifying the solvothermal reaction conditions for MOF synthesis, reaction of H\(_2\)bcpdmpm with Cu(NO\(_3\))\(_2\)·2½H\(_2\)O in a mixture of DMF, water and 70\% HNO\(_3\) at 85°C for 16 hrs gave green rod-like crystals of \{Cu\(_4\)(bcpdmpm)\(_2\)(EtOH)\(_2\)(H\(_2\)O)\(_2\)\}(NO\(_3\))\(_2\)·12DMF (2) suitable for X-ray crystallography. Due to the structural complexity and low density of the material, synchrotron radiation was required for single crystal and powder diffraction experiments. PXRD confirmed phase purity of the material (Figure 2, bottom).

MOF 2 crystallises in the monoclinic space group P2\(_1\)/c with a cell volume of 24480(2) Å\(^3\). The structure contains six independent copper atoms in total, four copper(II) centres that constitute two dinuclear paddlewheel units and two tetrahedral copper(I) centres. The latter were considered as Cu(I) centres as a tetrahedral geometry is far more common for d\(^{10}\) transition metals and CHN analysis supported the inclusion of only one nitrate.
anion per tetrahedral copper centre. Four molecules of ligand bcpppm complete the coordination requirements of the two copper(II) paddlewheel clusters, while each ligand chelates to a tetrahedral copper(I) centre via a di-pyrazolyl methane motif.

(c) A topological representation of the tetranodal four-connecting structure, approximately along the a axis, with the CuII paddlewheel nodes in red and tetrahedral CuI centres shown in blue.

The coordination of the paddlewheel copper(II) centres are completed by ethanol solvate molecules in the axial positions, but the nitrate counter-anions of the copper(I) centres could not be located in the difference map. The coordination chemistry of bcpppm and the resulting metal nodes are similar to that observed in the 2-D structure of 1, however the steric influence of the methyl groups in bcpppm disfavours formation of an octahedral copper(II) and hence an entirely different 3-D MOF structure is obtained.

During synthesis an in-situ reduction of copper(II) occurs. Such reductions are not uncommon in the solvothermal synthesis of coordination polymers and have been observed with ligands such as 2,2'-bipyridine (bpy) and di-2-pyridylamine. Methanol or ethanol can be responsible for the reduction of copper(II) under solvothermal conditions, although the identity of the reducing agent can be unclear. Furthermore, in some cases formation of the copper(I) assembly is reliant on the associated redox mediated modification of the ligand. Nonetheless, examples of mixed valence Cu(II)/Cu(I) coordination polymers are relatively rare, and a majority of these examples contain CN– or SCN– co-ligands. Based on literature precedent and the yield of the reaction (63%), the identity of the reducing agent is likely to be ethanol. The in-situ reduction is further supported by the angles about the tetrahedral copper centres of 2 which compare favourably to the bond angles of a known Cu(I) complex [Cu(bpy)2]ClO43.

The paddlewheel and tetrahedral copper centres both serve as four connecting nodes, leading to a self-interpenetrated tetranodal 4-connected 3-D structure (Figure 4). Self interpenetration is known though not commonly observed among MOF materials, and no reports exists of such materials being permanently porous. MOF 2 has a very low calculated density (0.890 cm3/g for the solvated material, ~0.6 cm3/g desolvated) and possesses distinct pores which can be seen along the a and b axes, while the c axis of the structure is essentially close-packed (Figure 4). Interestingly, a high density of copper(II) paddlewheels line the border of the rhombus-shaped pores along the b-axis (Figure 4d).

Taking into account the van der Waals radii of surrounding atoms and excluding the solvates coordinated to the paddlewheels, the pores along the b-axis measure 7.8 × 11.6 Å. Using the same methodology, the three distinct pores along the a-axis measure 3.6 × 3.9 Å, 5.0 × 8.8 Å, and 5.8 × 15.6 Å.

Post-synthetic structural changes and gas adsorption properties

A desolvated form of 1 ([Cu₂(C₄H₃(NO₃)₂)(bcppm)₂]·½CH₂Cl₂) was prepared by heating a dichloromethane (DCM) exchanged sample at 50°C overnight under high vacuum (Figure 2, top). Thermogravimetric analysis (TGA) of 1·½ showed a gradual loss of.
of 8.0% up to 250°C, at which point the steep drop in weight indicated decomposition of the material (Figure SI 2). The 1H NMR spectrum of a digested sample of 1ac did not show any chemical shifts due to solvent molecules (DMF, MeOH, DCM), while CHN analysis suggested the formulation \([\text{Cu}_2\text{Cu}^\text{II}_3\text{NO}_3\text{H}_{3}\text{O}_2\text{]}_2\text{bcppm}_2\text{H}_2\text{O}\). This is consistent with observations made when exposing activated samples to ambient conditions which resulted in an immediate colour change from olive green to light green, indicating coordination of the paddlewheel dimers by water molecules. Absorption of moisture by activated MOFs is commonly observed in the literature, especially in MOF materials composed of copper(II) paddlewheels.45

The PXRD of as-synthesised 1 was in good agreement with that simulated from the crystal structure, however the activated sample, 1ac, showed subtle shifts for the higher angle data, indicating a minor structural adjustment (Figure 2, top). As previously mentioned, the shortest contact between the 2-D layers arises from a van der Waals interaction between an apically coordinated DMF ligand and a molecule of bcppm from an adjacent layer and thus the structural change is likely to result from the loss of the DMF ligands from the copper(II) paddlewheel. Re-examination of the crystal structure of 1 with the paddlewheel solvent molecules removed reveals a channel along the 002 plane of the structure (Figure SI 1). These 1-D pores measure approximately 4.0 x 6.5 Å, which indicates that the desolvated material should adsorb both N2 and CO2, potentially with a high affinity for CO2 due to channels lined with unsaturated copper(II) metal sites.

A 77 K N2 isotherm performed in 1ac revealed a marginal gas uptake of (3.2 cm3/g at P/P0 = 0.94), while adsorption of CO2 at 195K gave a type I isotherm with a maximum uptake of 32.5 cm3/g at P/P0 = 0.95 (Figure SI 3). The BET and Langmuir surface areas were calculated from the 195 K CO2 isotherm using the criteria detailed by Walton and Snurr,46 giving values of 75.3 ± 0.9 m2/g and 110.0 ± 1.8 m2/g respectively. A noticeable hysteresis supports the presence of narrow channels in the structure of 1ac. At both 293 and 273 K, CO2 isotherms show a steep uptake at low pressures and total uptakes of 1.0 mmol (22.7 cm3/g) and 1.2 mmol (26.8 cm3/g) at 1200 mbar respectively. This isotherm profile and uptake is consistent with a combination of unsaturated Cu2+ sites and a small pore volume (Figure 5).47, 48

It is worth noting that high surface area copper(II) MOFs with exposed Cu2+ centres such as Cu-BTC,49 Cu-BTTri,50 and NU-10055 typically exhibit linear uptake of CO2 at 298 K. This suggests that the ratio of internal pore volume to density of exposed metal sites is important for enhanced low pressure CO2 adsorption. At 273 K, an expected linear uptake of N2 was observed, amounting to 0.13 mmol (3.0 cm3/g) at 1200 mbar (Figure 5). The low N2 uptake in the 77 and 273 K and negligible uptake 293 K suggests that the pore size of 1ac may be close to the kinetic diameter of N2.

The enthalpy of adsorption was calculated for 1ac, using the virial method,51 and afforded a value of -35.3 kJ/mol at low coverage (-36.1 kJ/mol using the Clausius-Clapeyron equation,52 Figure SI 4). This is in the lower range of enthalpy values for MOFs with open metal sites, which typically range from -21 to -62 kJ/mol for CO2.53, 54 However, the enthalpy is slightly higher than other MOFs with exposed copper(II) paddlewheels such as HKUST-1 (-30 kJ/mol)55 and CuBTTri (-21 kJ/mol).56 Due to the relatively low surface area of 1ac, the uptake capacity at room temperature (1.1 mmol/g) is significantly lower than that of HKUST-1 and CuBTTri, which have a maximum uptake of 4.7 mmol and 3.8 mmol at 1200 mbar and 1100 mbar respectively.

We also note that narrow limiting pore diameters can contribute to CO2 affinity.57, 58, 59

![Figure 5. CO2 and N2 isotherms for 1ac.](image)

Structural studies and TGA of 2 indicated that the material was potentially highly porous; thus experiments were carried out to access an activated form for gas adsorption studies. TGA experiments revealed a 63.9% weight loss due to solvent up to 130°C and that the material was thermally stable up to 260°C (Figure SI 5). Again, solvent exchange resulted in colour changes that were consistent with exchange of ligands at the axial coordination sites of the copper(II) paddlewheels. Heating a DCM exchanged sample at 50°C for 16 hrs gave the activated sample \([\text{Cu}_4\text{Cu}^\text{II}_\text{bcppm}]_2\text{BCTri}_{\text{I}}\text{NO}_3\text{H}_2\text{O}_{\text{I}}\) which was accompanied by a colour change of the crystals from blue to a light green colour. Desolvation was confirmed by a TGA trace of 2ac which showed a minimal weight loss of 2.7%.

Again, while phase purity of as-synthesised 2 had been confirmed, PXRD of 2ac indicated a significant structural change (Figure 2, bottom). The data showed a shift of the low angle Miller indices and a complete absence of higher angle diffraction indicating that a significant structural change occurs during desolvation. Initial gas adsorption measurements for 2ac revealed that the material was essentially non-porous to N2. CO2 uptake at 195 K gave a type I isotherm with a maximum uptake of 44.2 cm3/g at P/P0 = 0.99 (Figure SI 6). Based on the CO2 isotherm, the BET and Langmuir surface areas were estimated to be 149.3 ± 0.7 m2/g and 198.7 ± 0.9 m2/g, respectively. These values are well below the calculated geometric surface area (~3000 m2/g) and, along with PXRD data, suggest that a structural collapse occurred on activation. Other methods of activation were attempted, such as supercritical CO2 activation and freeze drying,60-62 however these were unfruitful. Furthermore, resolution of the activated material with various solvents did not regenerate the original structure indicating an irreversible structural transformation. To further elucidate the structural change, CO2 isotherms at 273 and 293 K were recorded (Figure SI 7). Both revealed a near linear uptake, which combined with
the low surface area of 2, suggests the absence of accessible unsaturated metal sites due to the structural transformation.

Conclusions

Here we have reported an extension of our approach for generating MOFs with restricted flexibility by describing two new copper-containing MOF materials that utilise a flexible ‘hinged’ bis-pyrazolylmethane ligand. With bcppm a 2-D layered MOF was obtained that upon activation yielded a permanently porous material. In contrast, a 3-D MOF was isolated from reactions of bpdpnm and Cu(NO)₂·2½H₂O. X-ray crystallography of 2 revealed a self-interpenetrated structure composed of Cu(II) paddlewheels and tetrahedral Cu(I) centres coordinated by the distinct donor sets within bpdpnm. Despite possessing large solvent accessible pores along the a and b axis, desolvation of the material yielded a relatively non porous form, with a notably different structure. MOF 1 showed a favourable adsorption for CO₂ over N₂ at room temperature which was rationalised by the relatively small pore diameter and the presence of unsaturated Cu²⁺ metal sites.

Both reported materials display different extents of structural flexibility in the solid-state and lie in different places on the classification continuum for flexible materials described by Kitagawa. MOF 1 undergoes slight structural changes upon desolvation but is probably best described as a 2ⁿ generation material, while MOF 2 is perhaps better considered as a 1ˢᵗ generation material (non-recoverable structural collapse) despite showing some porosity following its structural change. As shown in our previous and current work, the implementation of a methylene ‘hinge’ backbone impacts favourably on structural flexibility in MOF materials, however, this work also highlights that the flexibility is governed by the need for alterations in the coordination geometry around the metal ion coordinated by the ‘hinge’ donors. Importantly, this study also demonstrates that this class of hinged ligands can form metal nodes exclusively from one type of donor, giving rise MOF materials containing two distinct structural nodes. We are continuing to explore examples of this fascinating group of materials with respect to their gas adsorption properties.
