Disordered Control of Intestinal Sweet Taste Receptor Expression and Glucose Absorption in Type 2 Diabetes

Richard L. Young,2,3,4 Bridgette Chia,1,4 Nicole J. Isaacs,2 Jing Ma,2,5 Joan Khoo,2,6 Tongzhi Wu,2,3 Michael Horowitz,2,3 and Christopher K. Rayner2,3,4

We previously established that the intestinal sweet taste receptors (STRs), T1R2 and T1R3, were expressed in distinct epithelial cells in the human proximal intestine and that their transcript levels varied with glycemic status in patients with type 2 diabetes. Here we determined whether STR expression was (1) acutely regulated by changes in luminal and systemic glucose levels, (2) disordered in type 2 diabetes, and (3) linked to glucose absorption. Fourteen healthy subjects and 13 patients with type 2 diabetes were studied twice, at euglycemia (5.2 ± 0.2 mmol/L) or hyperglycemia (12.3 ± 0.2 mmol/L). Endoscopic biopsy specimens were collected from the duodenum at baseline and after a 30-min intraduodenal glucose infusion of 30 g/150 mL water plus 3 g 3-O-methylglucose (3-OMG). STR transcripts were quantified by RT-PCR, and plasma was assayed for 3-OMG concentration. Intestinal STR transcript levels at baseline were unaffected by acute variations in glycemia in healthy subjects and in type 2 diabetic patients. T1R2 transcript levels increased after luminal glucose infusion in both groups during euglycemia ([5.8 ± 10^4 copies] and [5.8 ± 10^4 copies, respectively) but decreased in healthy subjects during hyperglycemia (1.4 ± 10^4 copies). T1R2 levels increased significantly in type 2 diabetic patients under the same conditions ([+6.9 ± 10^4 copies). Plasma 3-OMG concentrations were significantly higher in type 2 diabetic patients than in healthy control subjects during acute hyperglycemia. Intestinal T1R2 expression is reciprocally regulated by luminal glucose in health according to glycemic status but is disordered in type 2 diabetes during acute hyperglycemia. This defect may enhance glucose absorption in type 2 diabetic patients and exacerbate postprandial hyperglycemia. Diabetes 62:3532–3541, 2013

Glucose in the small intestinal lumen induces feedback that regulates gastric emptying, absorptive function, and energy intake (1–3), mediated both by vagal nerve pathways and secretion of gut peptides (4), including glucose-dependent insulinotropic polypeptide (GIP) from enteroendocrine K cells and glucagon-like peptide 1 (GLP-1) from L cells. These “incretins” substantially augment insulin secretion when glucose is given orally compared with an isoglycemic intravenous infusion (5). The rate of gastric emptying and the secretion and action of the incretin hormones are both key determinants of postprandial glycemia. However, the precise mechanism of glucose detection in the small intestine remains unclear.

Lingual sweet taste cells possess two G-protein–coupled receptors, T1R2 and T1R3, which form a heterodimeric sweet taste receptor (STR) for sugars, D-amino acids, sweet proteins, and artificial sweeteners (6,7). T1R2/R3 activation liberates the α-subunit of the G-protein gustducin (α-gustducin), leading to intracellular Ca^{2+} release, gating of a taste-specific transient receptor potential ion channel TRPM5 (8), cellular depolarization, and release of mediators that activate lingual afferent nerves.

We, and others, have shown that STRs, α-gustducin, and TRPM5 are also expressed with cellular and regional specificity in the animal and human intestine, where they may serve as glucose sensors (4,9–13). In addition to expression in intestinal sweet taste cells, some of these taste components are also expressed in separate intestinal cell populations that detect umami (T1R3, α-gustducin, TRPM5), bitter, and fats (α-gustducin, TRPM5) (4). STR activation may be linked to gut hormone secretion, because mice deficient in T1R3 or α-gustducin exhibit defective glucose-induced GLP-1 release (14), whereas the STR blocker, lactisole, decreases GLP-1 secretion and increases glycemic excursions after intragastric or intraduodenal glucose infusion in humans (15,16). Animal studies also indicate that STR activation increases the availability and function of the primary intestinal glucose transporter, sodium-glucose cotransporter-1 (SGLT-1) (17,18), although this link has not been assessed directly in humans.

Patients with type 2 diabetes frequently demonstrate disordered gastrointestinal responses to nutrients, with delayed gastric emptying in up to 30–50%, abnormally rapid emptying in a few (19,20), and a high prevalence of gastrointestinal symptoms (21). GLP-1 and GIP secretion has been inconsistently reported to be diminished in patients with type 2 diabetes (22,23), whereas intestinal levels of SGLT-1 and the capacity for glucose absorption may be increased (24). Any of these abnormalities could potentially relate to disordered intestinal sensing of glucose. We previously reported that duodenal expression of STRs during fasting was comparable in unselected patients with type 2 diabetes and nondiabetic control subjects but was inversely related to the blood glucose concentration at the time of biopsy in type 2 diabetic patients (13). In rodents, we, and others, have also shown that intestinal STR transcript and protein levels are rapidly downregulated upon acute luminal exposure to glucose or artificial sweeteners (13,25). Our current aims were, therefore, to evaluate the modulation of duodenal STR expression in response to acute changes in luminal and systemic glucose exposure in healthy humans and to determine whether
STR regulation is disorder in type 2 diabetes and related to changes in glucose absorption and/or gut hormone secretion.

RESEARCH DESIGN AND METHODS

Subjects. Fourteen healthy subjects and 13 patients with type 2 diabetes were studied in randomized, crossover fashion. The mean duration of known diabetes in the latter group was 5 ± 1 years, HbA1c, was 6.3 ± 0.2% (45 ± 2 mmol/mol), and all were free of significant comorbidities and managed by diet alone. The protocol was approved by the Human Research Ethics Committee of the Royal Adelaide Hospital and conducted in accordance with the Declaration of Helsinki as revised in 2000. Each subject provided written informed consent.

Screening visit. Each subject attended the laboratory at 0830 h after an overnight fast of 12 h for solids and 10 h for liquids. An intravenous cannula was inserted for blood sampling, and subjects consumed a glucose drink (75 g glucose dissolved in water to 300 mL, labeled with 150 mg [14C]acetate) within 5 min (T = −5 to 0 min). Blood was sampled at T = −5, 30, 60, 120, and 180 min to measure blood glucose by a glucometer (Medisense Precision QID; Abbott Laboratories, Bedford, MA). Breath samples were collected before and every 5 min after oral glucose during the first hour, and every 15 min for a further 2 h to measure CO2 concentrations by isotope ratio mass spectrometer (ABCA 2020, Europa Scientific, Crewe, U.K.). The gastric half-emptying time was calculated using the formula of Ghooij et al. (25).

Gastrointestinal symptoms were assessed by a standard questionnaire (maximum score, 27), as previously described (27). Autonomic nerve function was assessed in the type 2 diabetes patients using standardized cardiovascular reflex tests, with a score ≥3 (of a maximum of 6) indicating autonomic dysfunction (28).

Endoscopy protocol. After the screening visit, each subject was studied twice, separated by at least a week, with female subjects excluded during the follicular phase of the menstrual cycle to limit variations in gut hormone secretion (29). Subjects attended the laboratory at 0830 h after an overnight fast, and an insulin/glucose clamp was established to achieve euglycemia (−5 mM/L) or hyperglycemia (−12 mM/L) (30). A 50-mL intravenous bolus of 25% glucose (Baxter Healthcare, Old Toongabbie, NSW, Australia) was administered on the hyperglycemic day, and 0.9% saline bolus of 25% glucose (Baxter Healthcare) on the euglycemic day, over 1 min each, followed by continued infusion of the same solution starting at 150 mL/h and adjusted according to blood glucose measurements every 5 min on the hyperglycemic day or remaining at 150 mL/h on the euglycemic day. On the euglycemic day, 25% dextrose was infused intravenously if the blood glucose concentration fell below 5 mM/L. In addition, 100 IU of insulin (Actrapid; Nordisk, Novo Nordisk, Ballumhills, NSW, Australia), in 500 mL 4% succinylated gelatin solution (Gelofusine; B. Braun Australia, Bella Vista, NSW, Australia), was administered on the hyperglycemic day, and 0.9% saline (Baxter Healthcare) on the euglycemic day, over 1 min each, followed by continuous infusion of the same solution starting at 150 mL/h and adjusted according to blood glucose measurements every 5 min on the hyperglycemic day or remaining at 150 mL/h on the euglycemic day. On the euglycemic day, 25% dextrose was infused intravenously if the blood glucose concentration fell below 5 mM/L. In addition, 100 IU of insulin (Actrapid; Novo Nordisk, Novo Nordisk, Ballumhills, Ballumhills, NSW, Australia), in 500 mL 4% succinylated gelatin solution (Gelofusine; B. Braun Australia, Bella Vista, NSW, Australia), was infused intravenously at a variable rate to maintain euglycemia. Once blood glucose concentrations were stable for 30 min (12.3 ± 0.2 mM/L on the hyperglycemic day or 5.2 ± 0.2 mM/L on the euglycemic day), a small diameter video endoscope (GIF-XP160; Olympus, Tokyo, Japan) was passed via an anesthetized nostril into the second part of the duodenum, from which mucosal biopsy specimens were collected using standard biopsy forceps and placed into RNA later (Qiagen, Sydney, NSW, Australia) or 4% parafomaldehyde for 2 h. At T = 0 an intraduodenal infusion containing 30 g glucose and 3 g glucose absorption marker 3-O-methylglucose (3-OMG; Sigma-Aldrich, St. Louis, MO) was commenced via the biopsy channel of the endoscope, and continued for 30 min (1 g/min; 4 kcal/min). At T = 10 and T = 30 min, additional biopsy specimens were collected. Blood samples (20 mL) were taken every 10 min or 1 h to determine concentrations of 3-OMG, C-peptide, GLP-1, and GIP.

Assays. Plasma total GLP-1 concentrations were measured by radioimmunoen assay (GLPT-36HK, Millipore, Billerica, MA) with sensitivity of 3 pmol/L and intra- and interassay coefficients of variation (CV) of 4.2% and 10.5%. Total plasma GIP was measured by radioimmunoassay as previously reported, with sensitivity of 2 pmol/L and intra- and interassay CV of 6.1% and 15.4%, respectively (31). Plasma C-peptide concentrations were measured by ELISA (10-1136-01, Mercodia, Uppsala, Sweden), with sensitivity of 15 pmol/L and intra- and interassay CV of 3.0% and 3.3%. Serum 3-OMG concentrations were measured by liquid chromatography and mass spectrometry, with sensitivity of 10 pmol/L (32).

Quantification of gene expression by real-time RT-PCR. RNA was extracted from tissues using an RNeasy Mini kit (Qiagen), following the manufacturer’s instructions, and RNA yield and quality were determined using a NanoDrop (NanoDrop Technologies, Wilmington, DE). Quantitative real-time RT-PCR was then used to determine the absolute expression of sweet taste molecules. Validated human primers for T1R2, α-gustducin, and TRPM5 were used as primer assays (QuantiTect, Qiagen). TIR3 primers were designed using Primer 3.0 software (Applied Biosystems, Foster City, CA) based on target sequences obtained from the National Center for Biotechnology Information nucleotide database (Table 1). Absolute standard curves were generated by including known copy number standards in RT-PCR for each target (Table 2), as described (13). RT-PCR was performed on a Chromol (MJ Research, Waltham, MA) real-time instrument attached to a PTC-200 Peltier thermal cycler (MJ Research) using a QuantiTect SYBR Green one-step RT-PCR kit (Qiagen) according to the manufacturer’s specification (33). One assay was performed in triplicate and included internal no-template and no-RT controls. All replicates were averaged for final mRNA copy number, which was expressed as copies/50 ng of total RNA.

Immunohistochemistry. Fixed tissues were cryoprotected (30% sucrose in PBS), embedded in cryomolds, and frozen before sectioning at 6–10 μm (Cryocut 1800; Leica Biosystems, Nussloch, Germany) and thaw mounting onto gelatin-coated slides. Immunoreactivity was detected using rabbit T1R2 primary (H90, 1:400, SC-50305; Santa Cruz Biotechnology, Santa Cruz, CA), goat GLP-1 primary (1:400, SC-7782; Santa Cruz Biotechnology), monoclonal 5-hydroxytryptamine (5-HT; 1:1000, M0758; Dako Australia, Victoria, Australia), and GIP primary antibodies (1:800, AB30679; Abcam). All were visualized using species-specific secondary antibodies conjugated to Alexa Fluor dyes (1:200 in PBS-Tween 20) as previously described (12,10). Antigen retrieval (S1700; Dako) was performed for T1R2 according to the manufacturer’s instructions. Nucleated epithelial cells immunopositive for individual targets were counted per square millimeter of high-power field and averaged over at least 10 intact transverse sections per subject.

Data analysis. The incremental area under the curve (IAUC) for 3-OMG, GLP-1, and GIP concentrations was calculated using the trapezoidal rule (33) and analyzed by one-factor ANOVA using Prism software (version 6.0; GraphPad Software Inc., La Jolla, CA). These variables were also assessed using repeated-measures ANOVA, with treatment and time as factors. Post hoc comparisons, adjusted for multiple comparisons by Holm-Sidak’s correction, were performed if ANOVAs showed significant effects. One-way ANOVA, with Holm-Sidak’s post hoc test, was used to compare differences in duodenal levels of STR transcripts between healthy subjects and type 2 diabetic patients. Relationships between transcript expression and other factors were evaluated by the Pearson correlation coefficient (r). We calculated that 12 subjects had 80% power to detect a one-third difference in duodenal TIR2 expression in paired studies (α = 0.05), compared with control (13). P values ≤ 0.05 were considered statistically significant. Data are expressed as mean ± SEM.

RESULTS

All subjects tolerated the study well. The patients with type 2 diabetes were older than the healthy subjects, but

QT, QuantiTect primer assay (Qiagen).
gastrointestinal symptom scores, BMI, and gastric emptying of glucose did not differ (Table 3). Five type 2 diabetic patients had autonomic dysfunction, but none had evidence of peripheral neuropathy, nephropathy, retinopathy, or macrovascular complications. As expected, blood glucose concentrations were higher in type 2 diabetic patients during fasting and after oral glucose (P < 0.05; Fig. 1A).

**Baseline STR expression.** Transcripts for T1R2, T1R3, α-gustducin, and TRPM5 were readily detected in duodenal biopsy specimens by quantitative RT-PCR. TRPM5 was the most abundant STR transcript in all subjects, with lower levels of α-gustducin and much lower levels of T1R2 and T1R3. T1R2 was the least expressed transcript (Fig. 2A). TRPM5 transcript levels in healthy subjects during euglycemia were 34 ± 8-fold higher than those of T1R2 (P < 0.001), whereas α-gustducin levels were 22 ± 7-fold higher (P < 0.05) and T1R3 levels were 12 ± 5-fold higher.

**Effects of acute changes in glycemia on STR expression.** Fasting expression of STR transcripts was unaffected by the glycemic state in healthy subjects or type 2 diabetes and did not differ between the groups (Fig. 2B–E).

**Effects of luminal glucose on duodenal STR expression.** Owing to intersubject variability in STR expression, responses to luminal glucose were evaluated as changes from baseline. During euglycemia, T1R2 transcript levels increased in response to duodenal glucose infusion in healthy and in type 2 diabetes after 30 min (+5.9 × 10⁴ and +5.8 × 10⁴ copies; Fig. 3A). During hyperglycemia, T1R2 transcript levels decreased in healthy subjects after 30 min (−1.4 × 10⁴ copies) but increased in type 2 diabetic patients (+6.9 × 10⁵ copies), so that levels in healthy were lower at 30 min during hyperglycemia than euglycemia and lower in type 2 diabetic patients during either glycemic state (subject × time interactions P < 0.01 for each). Levels of T1R3, α-gustducin, and TRPM5 transcript, in contrast, did not significantly change in response to luminal glucose under either glycemic condition (Fig. 3B–D).

**Plasma hormone concentrations.** Fasting plasma GLP-1 concentrations did not differ between healthy and type 2 diabetes and were not acutely affected by the glycemic state. Plasma GLP-1 increased in response to duodenal glucose infusion in all groups (P < 0.001; Fig. 1C), with higher concentrations evident in type 2 diabetic patients at 40 min irrespective of glycemic status (subject × time interactions P < 0.01) and at 50 min during euglycemia compared with healthy subjects (subject × time interactions P < 0.05). The iAUC for GLP-1 was higher in type 2 diabetic patients during euglycemia and hyperglycemia compared with healthy subjects (P < 0.05 each; Table 4). Fasting plasma GIP concentrations did not differ between healthy subjects and type 2 diabetic patients and were not acutely affected by the glycemic state. Plasma GIP increased in response to duodenal glucose infusion in both groups (P < 0.001; Fig. 1D), with higher GIP concentrations evident in type 2 diabetic patients at 40 min irrespective of glycemic status and higher concentrations during euglycemia at 20 and 50 min compared with healthy subjects (subject × time interaction P < 0.05). The iAUC was higher in type 2 diabetic patients during euglycemia compared with healthy subjects (P < 0.05; Table 4).

Fasting C-peptide concentrations were higher during hyperglycemia than during euglycemia in healthy subjects (P < 0.001; Fig. 1E) but not in type 2 diabetic patients. C-peptide concentrations increased in response to duodenal glucose infusion in both groups during hyperglycemia (subject × time interaction P < 0.05; iAUC P < 0.001) but not during euglycemia (Fig. 1E and Table 4). C-peptide concentrations during hyperglycemia were higher in healthy subjects than in type 2 diabetic patients throughout the

glucose infusion (subject × time interaction $P < 0.05$; iAUC $P < 0.001$).

Serum 3-OMG concentrations. Serum 3-OMG concentrations increased over time in all groups but were higher at 60 min in type 2 diabetic patients during hyperglycemia than in any other group (subject × time interaction $P < 0.001$; Fig. 1F). The iAUC for 3-OMG was higher in type 2 diabetic patients and in healthy subjects during hyperglycemia than during euglycemia ($P < 0.05$; Table 4).

Phenotype of human intestinal sweet taste cells. Immunolabeling for T1R2 was evident in single cells dispersed throughout the mucosal epithelium in healthy subjects and type 2 diabetic patients (Fig. 4). Immunopositive cells showed a homogenous distribution of the label throughout the cytoplasm, were largely open or “flask-shaped,” and were found with equal frequency within villi or crypts. In dual-labeling experiments in healthy subjects, 19 ± 11% of T1R2-labeled duodenal cells
coexpressed GLP-1, whereas 13 ± 8% of L cells coexpressed T1R2 (Fig. 4A). In a similar manner, 15 ± 10% of T1R2-labeled duodenal cells coexpressed GIP, whereas 12 ± 8% of K cells coexpressed T1R2 (Fig. 4B). Separate populations of T1R2-labeled cells coexpressed 5-HT (31 ± 6%), whereas 5 ± 1% of enterochromaffin (EC) cells coexpressed T1R2 in healthy subjects (Fig. 4C). During fasting, an equivalent number of T1R2 immunopositive cells were evident in healthy subjects and in type 2 diabetic patients, under euglycemia or hyperglycemia, and the

iAUC_{60}, incremental area under the curve at 60 min. Data are mean ± SEM. Significantly different from ^{a}healthy euglycemia, ^{b}healthy hyperglycemia, and ^{c}type 2 diabetes euglycemia.
number did not change during the duodenal glucose infusion. Similarly, the proportion of cells immunopositive for GLP-1, GIP, and 5-HT did not differ between healthy subjects and type 2 diabetic patients or with glycemic state or exposure to luminal glucose, although a trend for increased L cells in fasting type 2 diabetic patients was evident (data not shown; \( P = 0.07 \)).

**Relationships between variables.** Absolute copy numbers of STR transcripts during fasting and after the 30-min glucose infusion did not correlate with age, sex, BMI, symptom score, or gastric half-emptying time in either group, and in type 2 diabetic patients, they were not related to duration of diabetes, HbA1c, autonomic dysfunction, or symptom score. In contrast, the change in T1R2 transcript level after luminal glucose exposure correlated with the iAUC for 3-OMG in healthy subjects during euglycemia \(( r = 0.73, P < 0.05 \)) and the change in TRPM5 transcript level with plasma GLP-1 concentrations at 30 min \(( r = 0.62, P < 0.05 \)) in the same group. Changes in T1R2 \(( r = 0.78, P < 0.01 \)) and T1R3 transcript levels \(( r = 0.59, P < 0.05 \)) in type 2 diabetic patients during hyperglycemia also correlated with plasma GIP concentrations at 30 min, and the change in T1R2 correlated with the iAUC for GIP \(( r = 0.69, P < 0.05 \)).

**DISCUSSION**

This study is the first to define changes in expression of intestinal STR transcripts in healthy humans and patients with type 2 diabetes in response to acute changes in systemic and luminal glucose. We have shown that absolute levels of STR transcripts are unaffected by acute variations in glycemia during fasting in either group but that T1R2 expression increases upon exposure to luminal glucose during euglycemia. In contrast, T1R2 expression decreases markedly in response to luminal glucose during hyperglycemia in health but increases under the same conditions in type 2 diabetes. Type 2 diabetic patients also exhibit increased glucose absorption during acute hyperglycemia compared with healthy subjects, suggesting that dysregulated expression of intestinal STRs can perpetuate postprandial hyperglycemia in this group.

We confirmed our previous observation that fasting STR transcript levels are similar in health and in type 2 diabetes irrespective of age, sex, or BMI (13). Although we previously observed that levels of STR transcript were inversely related to fasting blood glucose concentrations in unselected type 2 diabetic patients presenting for endoscopy, we have now established unequivocally that acute changes in glycemia do not influence fasting intestinal STR expression in health or in “well-controlled” type 2 diabetes. The apparent discrepancy in these observations may reflect the effects of more longstanding hyperglycemia or differences in the duration of fasting in the earlier cross-sectional study. We have now shown that the intestinal STR system is, in contrast, highly responsive to the presence of luminal glucose, with rapid and reciprocal regulation of T1R2 transcripts in health, depending on the prevailing blood glucose concentration. Comparable changes were evident in T1R3 and TRPM5 transcript levels, although these were not statistically significant. Increased intersubject variability seen for T1R3 and TRPM5 transcript levels may be due to their expression in additional populations of intestinal cells tuned to detect other taste modalities and, therefore, unresponsive to luminal and/or systemic glucose.

Healthy subjects who displayed the largest glucose-induced increase in duodenal T1R2 transcript levels during euglycemia had the highest plasma concentrations of the glucose absorption marker 3-OMG. Because SGLT-1 is responsible for the active transport of luminal 3-OMG, our findings support a role of intestinal T1R2 signals in the regulation of glucose absorption via SGLT-1. Indeed, intestinal STR activation has been shown to upregulate SGLT-1 transcript, apical protein, and function in a number of species (17,18). Accordingly, reciprocal regulation of T1R2 in human health may increase SGLT-1 function at euglycemia to facilitate glucose absorption and reduce...
SGLT-1 function during hyperglycemia to limit postprandial glycemic excursion. However, despite a reduction in T1R2 transcript after luminal glucose exposure during hyperglycemia, our healthy subjects still displayed greater rates of glucose absorption than during euglycemia, which might be accounted for by changes in SGLT-1 lagging behind those in T1R2. Our finding that plasma 3-OMG concentrations were elevated in type 2 diabetic patients during hyperglycemia is in keeping with the concept that SGLT-1 transporter capacity was maintained, or increased, in the presence of luminal glucose under these conditions. In fact, even small changes in SGLT-1 may increase this risk, because type 2 diabetic patients are reported to have up to fourfold higher levels of transcript, protein, and function of this transporter at baseline compared with healthy control subjects (24). We note that an increased level of facilitated glucose transport via the basolateral glucose transporter GLUT2 may have contributed to plasma levels of 3-OMG in the current study; however, the role of STR signals to direct apical insertion of GLUT2 in enterocytes appears to be limited to rodents (25,34).

The link between STR stimulation and incretin hormone release in healthy humans is not clear. Most in vivo studies indicate that acute administration of nonnutritive sweeteners does not trigger incretin secretion in humans or rodents (35–37). Nonetheless, we observed that subsets of duodenal L cells, K cells, and EC cells were immunopositive for T1R2, in accord with previous reports (4,12,14). Together with positive associations between luminal glucose-induced changes in some STR transcripts and measures of GLP-1 and GIP secretion in the current study, it remains possible that STRs do have a regulatory role in gut hormone release. The inhibition of glucose-induced GLP-1 secretion in healthy humans by the STR blocker, lactisole (15), supports this concept. We also recognize that STR signals may serve autocrine and/or paracrine functions within the intestinal mucosa that are not reflected in circulating gut hormone concentrations; the latter appear to be a blunt marker for local concentrations of GLP-1 (38). There is also a large body of evidence indicating that the integrinotrophic gut peptide, glucagon-like peptide 2 (GLP-2), coreleased from L cells with GLP-1, is a powerful local stimulus to increase intestinal glucose transport via SGLT-1 and GLUT2 in rodents and in patients with short bowel syndrome (39–41). Importantly, GLP-2 release has recently been revealed as STR-dependent in animals and in a human enteroendocrine cell line (42,43), highlighting an important link between STRs and GLP-2 in the regulation of intestinal glucose transport.

Reports concerning postprandial incretin hormone release in patients with type 2 diabetes have been inconsistent, with plasma GLP-1 concentrations after a mixed meal being either reduced (22) or intact (44), although such studies are potentially confounded by failure to control for differences in the rate of gastric emptying, which is frequently delayed in longstanding diabetes or during acute hyperglycemia (20). Our observation that GLP-1 and GIP responses to a standardized rate of duodenal glucose infusion were maintained, and indeed increased, in type 2 diabetic patients, supports our previous findings (45) and is in keeping with the trend for increased L-cell density in these patients in the current study and a report of an increased density of L cells and mixed L/K cells in the duodenum of well-controlled type 2 diabetic patients (46). There is now strong evidence that SGLT-1 transport is a key stimulus for release of GLP-1 and GIP, which occurs even after exposure to nonmetabolized SGLT-1 substrates and is inhibited by pharmacological blockade or genetic ablation of SGLT-1 in rodents (47–49). Therefore, increased SGLT-1 capacity could explain enhanced glucose-induced GLP-1 and GIP responses in our type 2 diabetic patients. Any deficiency in the incretin effect in type 2 diabetes is likely to be explained by impaired β-cell function rather than by deficient incretin hormone secretion (45,50), and indeed, defective C-peptide responses in our type 2 diabetic patients during hyperglycemia support this assertion. Acute hyperglycemia had no effect on GLP-1 or GIP secretion, as noted previously (51,52). Although SGLT-1 transport appears a major determinant of GLP-1 and GIP release, other transporters (49,53) or signaling pathways (54) may also be involved, so increased glucose absorptive capacity during hyperglycemia may not necessarily result in enhanced GLP-1 or GIP concentrations.

Our study had a number of limitations. Transcriptional regulation of intestinal T1R2 occurred rapidly in humans, but we did not quantify changes in STR protein in parallel due to ethical considerations on the additional biopsy specimens required. However, similarly rapid changes in these proteins after glucose or sucralose exposure are known to occur in apical membrane vesicles of rat jejunum (25). We did not assess effects on SGLT-1 transcript or protein here, although measures of glucose absorption with 3-OMG reflect, in large part, SGLT-1 function as the primary intestinal glucose transporter in humans. There was considerable interindividual variability in baseline expression of intestinal STR transcripts, so that our study was insufficiently powered to detect relationships between absolute transcript levels and concentrations of gut hormones and 3-OMG. Our 3-OMG measurements were limited to 60 min, and differences between groups or glycemic states might have become more marked after this point. The duodenal glucose infusion was also relatively brief, being limited by the tolerability of unsedated endoscopy. Our type 2 diabetic patients had relatively good glycemic control, and more marked differences from health might be observed in patients with a higher HbA1c. The type 2 diabetic patients were older than the healthy control subjects, although we have not previously shown any age-related differences in postprandial GLP-1 responses (55).

In conclusion, we have shown that the intestinal STR system is reciprocally regulated in the presence of luminal glucose according to glycemic status in health but not in type 2 diabetes. In the latter, T1R2 dysregulation potentially increases the risk of postprandial hyperglycemia, but the intestinal STR system appears unlikely to be a major determinant of circulating GLP-1 or GIP concentrations in humans.

ACKNOWLEDGMENTS

This study was supported by grants awarded to R.L.Y. by the National Health and Medical Research Council (NHMRC) of Australia (grant no. 627127) and to R.L.Y., M.H., and C.K.R. from Diabetes Australia. T.W. was supported by an NHMRC Overseas (Clinical Postdoctoral Training Fellowship (grant no. 519349).

No potential conflicts of interest relevant to this article were reported.

R.L.Y. and C.K.R. conceived, designed, and supervised the study, obtained funding, acquired data, undertook
statistical analyses and interpreted data, and drafted and critically reviewed the manuscript. B.C. and N.J.I. acquired data and provided technical support. J.M., J.K., and T.W. assisted in study design, acquired data, and critically reviewed the manuscript. M.H. designed the study, interpreted data, and critically reviewed the manuscript. R.L.Y. and C.K.R. are the guarantors of this work and, as such, had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

The authors thank the Endoscopy Unit staff, Department of Gastroenterology and Hepatology, Royal Adelaide Hospital, for their assistance with the study; Dr. Kate Sutherland, University of Sydney, for contributing to the molecular assays in this study; and Kylie Lange, National Health and NHMRC Centre of Research Excellence in Translating Nutritional Science to Good Health, University of Adelaide, for professional biostatistical support.

Preliminary accounts of this study were presented at the Digestive Disease Week meeting of the American Gastroenterological Association, Chicago, IL, 7–11 May 2011; and at the Joint International Neurogastroenterology & Motility Meeting, Bologna, Italy, 6–8 September 2012.
